Application of Signomial Programming to Aircraft Design

Philippe G. Kirschen,∗ Martin A. York,† Berk Ozturk,‡ and Warren W. Hoburg§
Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

Due to the coupled nature of aircraft design, it is important to consider all major subsystems when optimizing a configuration. This is difficult when each individual subsystem model can be arbitrarily complex. By restricting an optimization problem to have a certain mathematical structure, significantly more effective and tractable solution techniques can be used. Geometric programming, one such technique, guarantees finding a globally optimal solution. Although it has been shown that geometric programming can be used to solve some aircraft design problems, the required formulation can prove too restrictive for certain relationships. Signomial programming is a relaxation of geometric programming that offers enhanced expressiveness. Although they do not guarantee global optimality, solution methods for signomial programs are disciplined and effective. In this work, signomial programming models are proposed for optimal sizing of the wing, tail, fuselage, and landing gear of a commercial aircraft. These models are combined together to produce a system-level optimization model. Signomial programming’s formulation allows it to handle some key constraints in aircraft design, and therefore an improvement in fidelity over geometric programming models is achieved. A primary contribution of this work is to demonstrate signomial programming as a viable tool for multidisciplinary aircraft design optimization.

I. Introduction

GEOMETRIC programming (GP) is an optimization technique that combines the expressiveness of nonlinear objectives and constraints with the mathematical rigor of convex optimization to provide a powerful approach to solving multidisciplinary aircraft design optimization problems. For problems that can be formulated as geometric programs (GPs), modern solvers guarantee globally optimal solutions, are extremely fast, and return local sensitivities at no extra cost, thanks to the principle of Lagrange duality. In previous work, Hoburg and Abbeel [1] showed that many models common to aircraft design can be represented directly in GP-compatible form and that there are a number of innovative ways of dealing with models that cannot, including (but not limited to) changes of variables and GP-compatible fitting methods. Finally, it is also shown that such problems can be solved efficiently using a standard laptop computer. The aircraft design problem solved in [1] includes models for steady level flight, range, takeoff, landing, a sprint flight condition, actuator disk propulsion efficiency, simple drag and weight buildups, and a beam wing box structure.

Because of these promising initial results, there is a strong desire to extend the use of GP for aircraft design, both in breadth, by considering more aspects of the aircraft design problem, and in depth, by increasing the fidelity of the models used. Unfortunately, the restrictions of the GP formulation mean that not all aircraft design constraints can be readily implemented as part of a GP. A generalization of GP called signomial programming (SP) helps to address this by allowing constraints with less restrictive formulations [2]. A relatively small relaxation in the restriction on problem formulation means that SP can handle a significantly more-general set of problems than GP, but this comes at a cost; SP does not boost the same guarantee of global optimality as GP. Despite this, solution methods remain disciplined and effective by leveraging a difference of convex program formulation for SP.

Signomial programming is important for aircraft design because it allows a modeler to leverage the speed and reliability of GP on models that are not GP-compatible, and it enables increasing fidelity where it is not possible to maintain GP-compatibility. From the authors’ limited experience, only a small proportion of the constraints in aircraft design models require signomials, if any. In many cases, however, omitting these constraints would mean failing to capture an important design consideration. Sometimes, the constraint in question is the only constraint that keeps one or more design variables meaningfully bounded. Thus, optimization quality and robustness are sacrificed in exchange for obtaining dual feasibility and/or higher model fidelity. It is important to stress that the purpose of this work is not to use SP liberally but rather to use it in a targeted and precise manner, where the marginal cost of introducing a signomial constraint can be justified by an adequate increase in model fidelity or accuracy. Because they result in convex restrictions on the feasible set, monomial and posynomial constraints are still viewed as the preferred approach wherever possible.

There exists extensive research in multidisciplinary design optimization (MDO) methods for conceptual aircraft design [3–7]. Of the many different frameworks in the literature, TASOPT [8] is particularly relevant to the present work because of its use of physics-based models, medium-fidelity analytical models, and multidisciplinary considerations of aircraft subsystems. Common challenges faced in multidisciplinary design optimization include models that are too computationally expensive to be practical for a designer, final results that are sensitive to the choice of baseline design, evaluations of black box functions that offer optimizers little-to-no visibility of exploitable mathematical structure, and coupling of different analysis tools that require delicate wiring between models and generally another layer of complexity and opacity.

In the following sections, SP models are presented for design of the wing, vertical tail, horizontal tail, fuselage, and landing gear of a conventional tube-and-wing commercial aircraft. These models can be used to determine optimal values for, among other things, the preliminary geometry, positioning, and weight of each subsystem. They are compilations of constraints, some developed by the authors and others obtained from a variety of references. As a result, the relationships are not necessarily original, but their adaptation to
signomial programming is. Each model is readily extensible, meaning that constraints can be added and made more sophisticated with ease.

Each section of this paper describes a model, beginning with the key assumptions regarding the model, followed by the enumeration and description of the constraints. The intention is to demonstrate the wide range of aircraft design constraints that fit naturally into the signomial programming formulation.

The models are combined together in a full-configuration system-level model that captures the highly coupled nature of aircraft design. This model is solved using estimates for fixed variables based on a reference aircraft, the Boeing 737-800. Although the emphasis of this work is not on the solution, it does allow us to verify that the full-system model has a solution that is not only feasible but also credible. To the authors’ best knowledge, this is the first published work on SP applied to aircraft design.

Before presenting these models, we begin with brief introductions to both geometric and signomial programming.

A. Introduction to Geometric Programming

First introduced in 1967 by Duffin et al. [8], a GP is a specific type of constrained, nonlinear optimization problem that becomes convex after a logarithmic change of variables. Modern GP solvers employ primal-dual interior point methods [9] and are extremely fast. A typical sparse GP with tens of thousands of decision variables and one million constraints can be solved on a desktop computer in minutes [2]. Furthermore, these solvers do not require an initial guess and guarantee convergence to a global optimum, whenever a feasible solution exists. Being able to find optimal solutions without an initial guess makes the technique particularly useful for conceptual aircraft design, where it is important that results are not biased by preconceptions of how an optimal aircraft should look.

These impressive properties are possible because GPs represent a restricted subset of nonlinear optimization problems. In particular, the objective and constraints can only be composed of monomial and posynomial functions.

A monomial is a function of the form:

$$ m(x) = e \prod_{j=1}^{n} x_j^{a_j} $$

where $a_j \in \mathbb{R}$, $e \in \mathbb{R}_{+,1}$, and $x_j \in \mathbb{R}_{+,1}$. For instance, the familiar expression for lift, $(1/2) \rho V^2 C_L S$, is a monomial with $x = (\rho, V, C_L, S)$, $e = 1/2$, and $a = (1, 2, 1, 1)$.

A posynomial is a function of the form:

$$ p(x) = \sum_{k=1}^{K} c_k \prod_{j=1}^{n} x_j^{a_{jk}} $$

where $a_{kj} \in \mathbb{R}^+$, $c_k \in \mathbb{R}_{+,1}$, and $x_j \in \mathbb{R}_{+,1}$. Thus, a posynomial is simply a sum of monomial terms, and all monomials are also posynomials (with just one term).

In plain English, a GP minimizes a posynomial objective function, subject to monomial equality constraints and posynomial inequality constraints. The standard form of a geometric program in mathematical notation is as follows:

minimize $p_0(x)$

subject to $p_j(x) \leq 1$, $j = 1, \ldots, n_p$.

$m_k(x) = 1$, $k = 1, \ldots, n_m$ (3)

where $p_j$ are posynomial (or monomial) functions, $m_k$ are monomial functions, and $x \in \mathbb{R}_{+,1}^n$ are the decision variables.

Although this form may appear restrictive, surprisingly many physical constraints and objectives can be expressed in the necessary form [1]. Many relationships that cannot be formulated exactly as posynomials can be approximated closely, using methods for fitting GP-compatible models to data [10].

B. Introduction to Signomial Programming

Geometric programming is a powerful tool, with strong guarantees. As discussed previously however, the formulation can prove restrictive. Although changes of variable present an elegant way of circumventing some formulation obstacles, there may not always exist a suitable variable change. In particular, the restriction $e > 0$ in the definition of a posynomial can be a prohibitive obstacle for a model. There are many models where being able to use negative coefficients is necessary to accurately capture a relationship, such as when trying to minimize the difference between two quantities. An example of this is Lock’s empirical relationship for wave drag [11] that is commonly used in conjunction with the Korn equation to estimate the drag on a transonic wing:

$$ C_{D_{wave}} \geq 20(M - M_{ crit})^3 $$

A signomial is a function with the same form as a posynomial:

$$ s(x) = \sum_{k=1}^{K} c_k \prod_{j=1}^{n} x_j^{a_{jk}} $$

except that the coefficients $c_k \in \mathbb{R}$ can now be any real number. In particular, they can be nonpositive. A signomial program is a generalization of a geometric program that allows signomial constraints. The “difference of convex” formulation of a signomial program also permits the objective function to be a ratio of signomials and is given by:

minimize $p_0(x)$

subject to $s_j(x) \leq 0$, $j = 1, \ldots, n_s$.

$p_j(x) \leq 1$, $j = 1, \ldots, n_p$.

$m_k(x) = 1$, $k = 1, \ldots, n_m$ (6)

Although Eq. (6) is standard form for a signomial program, the majority of signomial constraints presented in this work take the form $p_j(x) \leq s_j(x) \leq p(x)$ because these are often more intuitive and both can easily be transformed into the standard form $s(x) \leq 0$. This follows the geometric programming convention of using posynomial inequality constraints of the form $p(x) \leq m(x)$ and monomial equality constraints of the form $m_k(x) = m_k(x)$ [2].

Sometimes there is both upward and downward (optimization) pressure on a variable, and it is not always possible to know a priori which will dominate. In these cases, we can use signomial equality constraints of the form $s(x) = 0$. However, as discussed in the next section, these constraints are generally less desirable than signomial inequality constraints from an optimization perspective. We therefore use them as sparingly as possible in this work.

An important point is that adding just one signomial constraint to a geometric program with arbitrarily many posynomial constraints changes the geometric program to a signomial program.

The bad news is that the increased expressiveness of signomial programming comes at a price; we can no longer guarantee a global optimum because, unlike with GP, the log transformation of a signomial program is not a convex optimization problem. The good news is that there is a disciplined method for solving signomial programs (SPs).

C. Signomial Programming Solution Methods

There are a number of different methods for solving SPs. The majority of heuristics involve finding a local GP approximation to the SP about an initial guess $x^0$, solving this GP, and then repeating the process, using the previous iteration’s optimal solution as the point about which to take the next GP approximation. The process is repeated until the solution converges [2, 12]. The GP approximation is obtained by approximating each signomial constraint with a posynomial constraint.
The first step, if it has not already been done, is to express each signomial, \( s_i(x) \), as a difference of posynomials, \( p_i(x) \) and \( q_i(x) \), and rearrange them to the form of a posynomial less than or equal to another posynomial:

\[
\begin{align*}
  s_i(x) &\leq 0 \quad (7) \\
  p_i(x) - q_i(x) &\leq 0 \quad (8) \\
  p_i(x) &\leq q_i(x) \quad (9)
\end{align*}
\]

Although Eq. (9) is not a GP-compatible constraint, it can be made into a GP constraint if posynomial \( q_i(x) \) is replaced with its local monomial approximation \( \hat{q}_i(x; x^0) \), because a posynomial divided by a monomial is also a posynomial:

\[
\hat{p}_i(x) = \frac{\hat{q}_i(x; x^0)}{\hat{q}_i(x; x^0)} \leq 1 \quad (10)
\]

Filling a monomial approximation to a posynomial is analogous to finding a local affine approximation to a nonlinear function in log space. The best-possible local monomial approximation to a posynomial \( q_i(x) \) at the point \( x^0 \) \[2\] is given by:

\[
\hat{q}_i(x) = q_i(x^0) \prod_{n=1}^{N} \left( \frac{x_n}{x_n^0} \right)^{a_n} \quad (12)
\]

where \( x_n \) are the elements of \( x \) and

\[
a_n = \frac{x_n^0}{\hat{q}_i(x^0)} \frac{\partial \hat{q}_i}{\partial x_n} \quad (13)
\]

Signomial programming, using formulation (6), is an example of difference of convex programming because the logarithmically transformed problem can be expressed as:

\[
\begin{align*}
  \text{minimize} & \quad f(x) - g(x) \\
  \text{subject to} & \quad f_i(x) - g_i(x) \leq 0, \quad i = 1, \ldots, m
\end{align*}\quad (14)
\]

where \( f_i \) and \( g_i \) are convex. This means that, for the convex (GP) approximation \( f(x) \) of the nonconvex (SP) function \( f(x) - g(x) \),

\[
\hat{f}(x) \geq f(x) \quad \forall x \quad (15)
\]

Because of this, the true feasible set contains the feasible set of the convexified problem, and there is no need for a trust region \[13\], meaning that there is no need to tune solver parameters for controlling initial trust region sizes and/or update rules.

Signomial equality constraints are solved by creating local monomial approximations to the equality constraint. Unfortunately, the feasible set of the monomial approximation is not a subset of the original feasible set. Therefore, signomial equality constraints may require a trust region, making them the least desirable type of constraint. However, the signomial equality constraints in this work did not require a trust region, and thus parameter tuning was not necessary. For additional details on how signomial equalities are implemented, see Oppenood et al. \[14\].

The models solved in this paper employ a relaxed constants penalty function heuristic. This heuristic is a minor variation on the penalty convex–concave procedure described by Lipp and Boyd \[12\]. The heuristic employs the previously discussed iterative process; however, every constant in the model, \( c_i \), is paired with a relaxed constant, \( \tilde{c}_i \). Slack variables, \( s_i \), are introduced to facilitate the variation of the relaxed constants in accordance with Eqs. (16–18):

\[
\begin{align*}
  s_i &\geq 1 \quad (16) \\
  c_i &\geq \frac{\tilde{c}_i}{s_i} \quad (17) \\
  c_i &\leq \tilde{c}_i s_i \quad (18)
\end{align*}
\]

The original objective function for each individual GP, \( f(x) \), is modified to give a new objective function \( g(x) \) that heavily penalizes slack variables greater than 1:

\[
g(x) = \left( \prod_{i=1}^{N} s_i \right)^{20} f(x) \quad (19)
\]

The large penalty on slack in the objective function ensures that slack variables equal 1 when the SP converges. In other words, when the relaxed SP converges it is identical to the original model. The introduction of slack variables is advantageous because it allows early GP iterations to move through regions that are infeasible in the original model, reducing solution time while increasing model stability. It was observed in practice that the relaxed constants penalty method used in this paper was faster than the penalty convex concave procedure detailed in \[12\] because it involved introducing fewer additional variables, allowing the model to build faster.

The models presented in this work are composed and solved using GPKit \[15\], a Python package for defining and manipulating geometric programming models, with MOSEK \[16\] as the backend solver.

II. System-Level Model

The objective of the optimization problem presented in this work is to minimize fuel consumption, or equivalently fuel weight \( W_{\text{fuel}} \), using an adaptation of the Breguet range formulation introduced in \[1\]. The purpose of the system-level model is threefold; it enforces system-level performance constraints such as required range and minimum cruise speed, it encodes weight and drag buildsups, and it constrains system-level properties such as the aircraft’s c.g. and moment of inertia. In doing these things, it also couples the subsystem models.

A. Model Assumptions

The model presented in this work is a set of constraints that describe the performance and design of a conventional-configuration narrowbody aircraft, with a simple cruise-only mission profile. A more sophisticated mission profile is left for future work.

B. Model Description

Tables 1 and 2 list the free and fixed variables used in the system-level constraints.

1. Flight Performance

The Breguet range formulation is discretized over multiple cruise segments to improve accuracy as the aircraft weight changes, meaning every constraint is applied during each of the \( n = 1 \ldots N \) flight segments. For readability, the \( n \) subscripts are not used in the remainder of the manuscript, but still apply.

The sum of the cruise segment ranges must be greater than or equal to the required range of the aircraft. This is enforced using a signomial constraint:

\[
\sum_{n=1}^{N} R_n \geq R_{\text{req}} \quad (20)
\]

A series of \( N - 1 \) monomial equalities constrain all of the flight segments to be of equal length, which is helpful for applying the model to more sophisticated mission profiles.

\[
R_1 = R_2 = \ldots = R_N \quad (21)
\]
The Breguet range relationship is enforced with GP-compatible constraints, using a dummy variable, as done in [1].

\[
W_{\text{fuel}} \geq \left(z_{\text{bne}} \cdot \frac{1}{2} + \frac{z_{\text{bne}}}{6}\right)W_{\text{end}}
\]

\[
z_{\text{bne}} \geq c_{\text{f}} t_{\text{b}} \frac{D_{n}}{W_{\text{avg}}}
\]

\[
W_{\text{avg}} \geq \sqrt{W_{\text{start}} W_{\text{end}} + W_{\text{buoy}}}
\]

The aircraft weight at the start of cruise is assumed to equal its maximum weight, which comprises dry weight, payload weight, and fuel weight, including a reserve requirement. The weight lost during each segment is equal to the weight of the fuel burned during that segment. These relationships are enforced using a series of monomial and posynomial constraints:

\[
W_{\text{start}} = W_{\text{max}}
\]

\[
W_{\text{start}} \geq W_{\text{end}} + W_{\text{fuel}}
\]

\[
W_{\text{start}_{t+1}} = W_{\text{end}}
\]

\[
W_{\text{end}} \geq W_{\text{dry}} + W_{\text{pay}} + f_{\text{fuel}} W_{\text{fuelus}}
\]

\[
W_{\text{max}} \geq W_{\text{dry}} + W_{\text{pay}} + W_{\text{fuelus}} \cdot (1 + f_{\text{fuel}})
\]

\[
W_{\text{fuelus}} \geq \sum_{n=1}^{N} W_{\text{fuel}_n}
\]

The dry weight and drag of the aircraft are constrained using simple buildups of each component’s weight and drag:

\[
W_{\text{dry}} \geq W_{\text{wing}} + W_{\text{fuse}} + W_{\text{vt}} + W_{\text{ht}} + W_{\text{lg}} + n_{\text{eng}} W_{\text{eng}} + W_{\text{misc}}
\]

\[
D_{n} \geq D_{\text{wing}} + D_{\text{fuse}} + D_{\text{vt}} + D_{\text{ht}}
\]

Mach number is constrained to be greater than a user-specified minimum value, to represent, for example, an operational requirement:
\[ M = \frac{V_w}{a} \]  
\[ M \geq M_{\text{min}} \]  
\[ x_{\text{TO}} \leq l_r \]  
\[ 1 + y \leq 2 \frac{g \gamma \omega_{\text{TO}}}{V_{\text{TO}}^2 W_{\text{max}}} \]  
\[ 1 \geq 0.0464 \frac{g^2 \sigma_C}{\gamma^2 \sigma} + 1.044 \frac{g^3 \sigma_C}{\gamma^3 \sigma} \]  
\[ \xi \geq \frac{1}{2} \frac{\rho \gamma \omega_{\text{TO}} \bar{S}_w C_D}{\gamma_{\text{TO}}} \]  
\[ V_{\text{TO}} = 1.2 \sqrt{\frac{2 W_{\text{max}}}{C_{L_{\text{cruise}} \bar{S}_w \rho_{\text{TO}}}}} \]  

Atmospheric pressure, density, temperature, and speed of sound are constrained using the atmosphere model described in [18]. Dynamic viscosity is constrained using the viscosity model developed in [19], which is based on the Sutherland viscosity model [20].

2. System-Level Properties

The constraint for the aircraft c.g. is GP-compatible and is applied for each flight segment. The fuselage and payload weights are assumed to be evenly distributed through the length of the fuselage, and the wing weight acts directly at its area centroid, \( x_{\text{wing}} + \Delta x_{\text{ac}} \). It is assumed that the fuel weight shifts in proportion to the remaining fuel fraction \( f_{\text{fuel}} \) and that a reserve fuel fraction \( f_{\text{fuel}} \) remains in the wing. The wing box forward bulkhead location \( x_b \) is used as a surrogate variable for engine c.g.:

\[ W_{\text{end}} x_{\text{CG}} \geq W_{\text{wing}} (x_{\text{wing}} + \Delta x_{\text{ac}}) \]
\[ + W_{\text{fuel}} (f_{\text{fuel}} + f_{\text{fuel}}) (x_{\text{wing}} + \Delta x_{\text{ac}}, f_{\text{fuel}}) \]
\[ + \frac{2}{3} (W_{\text{fuselage}} + W_{\text{pay}}) (f_{\text{fuel}} + f_{\text{fuel}}) \]
\[ + \bar{W}_{\text{ac}} x_{\text{ac}} + W_{\text{fuselage}} x_{\text{fuselage}} \]
\[ + n_{\text{eng}} W_{\text{eng}} x_b + W_{\text{fuselage}} x_{\text{fuselage}} + W_{\text{misc}} x_{\text{misc}} \]  

\[ f_{\text{fuel}} \geq \frac{\sum_{n=1}^{n} W_{\text{end}}}{W_{\text{end}}} \]  

The landing-gear c.g. is constrained by the moment of each set of landing gear about the nose of the aircraft:

\[ W_{\text{ac}} x_{\text{CG}} \geq W_{\text{ac}g} x_{\text{acg}} + W_{\text{eng}} x_{\text{eng}} \]  

The miscellaneous equipment c.g. includes only power systems in the current model but is defined to allow for refinements in c.g. modeling in future work:

\[ W_{\text{misc}} x_{\text{misc}} \geq W_{\text{misc}} x_{\text{misc}} \]  

The aircraft’s moment of inertia is the sum of the moments of inertia of its major components:

\[ I_z \geq I_{\text{wing}} + I_{\text{fuel}} + I_{\text{rad}} \]  

The wing moment of inertia model includes the moment of inertia of the fuel systems and engines. It assumes that the wing and fuel weight are evenly distributed on the planform of the wing. This is an overestimate of the wing moment of inertia with full fuel tanks:

\[ I_{\text{wing}} \geq \frac{\bar{W}_{\text{wing}} x_{\text{wing}}^2}{g} + \left( \frac{W_{\text{fuel}} x_{\text{fuel}} + W_{\text{wing}}}{g} \right) \frac{b^2 c_{\text{root}}}{165 \bar{S}_w} \left( I_w + \frac{1}{3} \right) \]  

The fuselage moment of inertia includes the payload moment of inertia. It is assumed that payload and fuselage weight are evenly distributed along the length of the fuselage. The wing root quarter-chord location acts as a surrogate for the c.g. of the aircraft:

\[ I_{\text{fuselage}} \geq \left( \frac{W_{\text{fuselage}} + W_{\text{payload}}}{g} \right) \frac{x_{\text{wing}}^2 + I_{\text{fuselage}}}{3 l_{\text{fuselage}}} \]  

The moment of inertia of the tail is constrained by treating the tail as a point mass:

\[ I_{\text{rad}} \geq \left( W_{\text{turb}} + W_{\text{fuel}} + W_{\text{in}} \right) l_{\text{t}}^2 \]  

III. Wing Model

The overarching purpose of an aircraft wing is to generate sufficient lift such that the aircraft can take off, climb, cruise, descend, and land safely. Typically, the wings also carry fuel tanks and support the engines. Unfortunately, wings are heavy and produced drag. The purpose of this model is to capture all of these considerations.

A. Model Assumptions

The wing model assumes a continuous-taper, low-wing configuration with a modern transonic airfoil. It does not currently consider wing twist or wing dihedral. It also does not consider roll or yaw stability.

B. Model Description

The wing model has 52 free variables and 49 constraints. Tables 3 and 4 list the model’s free and fixed variables, respectively.

1. Wing Geometry

Before considering a wing’s performance, the variables that prescribe its geometry must be appropriately constrained. The variables that define the wing geometry are illustrated in Fig. 1, using an adaptation of a figure from [21].

The relationship between reference area, span, and mean geometric chord is enforced using a constraint that assumes a trapezoidal planform. This constraint is implemented as a signomial equality constraint because there is both upward and downward (optimization) pressure on the reference area, and it is not possible to know a priori which will dominate:

\[ S_w = b_w \frac{c_{\text{root}} + c_{\text{tip}}}{2} \]  

The mean aerodynamic chord relationship for a trapezoidal wing can be written as a posynomial constraint, and its spanwise location can be written as a monomial equality constraint. These constraints make use of dummy variables \( p_w \) and \( q_w \), introduced by the structural model, as follows:

\[ \tilde{c}_w \geq \frac{2}{3} \left( \frac{1 + \lambda_w^2}{q_w} \right) c_{\text{root}} \]

| $t_{\text{web}}$ |       | Nondimensional spar web thickness |

\[
y_{\text{w}} = \frac{b_w q_w}{3 \rho_w} \tag{53}
\]

The wing taper ratio is defined by a monomial equality constraint. It is necessary to lower bound taper to avoid an unacceptably small Reynolds number at the wing tip [22]. For the purpose of this work, the taper is lower-bounded using the taper ratio of the reference aircraft’s wing [23]:

\[
\lambda_{\text{w}} = \frac{\epsilon_{\text{tip}}}{c_{\text{root},w}} \tag{54}
\]

\[
\lambda_{\text{w}} \geq \lambda_{\text{w,\text{min}}} \tag{55}
\]

Finally, a maximum span constraint can be imposed to reflect, for example, a gate size constraint:

\[
b_w \leq b_{w,\text{max}} \tag{56}
\]

2. Wing Lift

Total lift is constrained to be greater than the weight of the aircraft plus the downforce from the horizontal tail. The constant $f_{L_{\text{total}}/L_{\text{w}}}$ is greater than 1 and used to account for fuselage lift:

\[
L_{\text{total}} \geq W_{\text{avg}} + L_{\text{ht}} \tag{57}
\]

\[
L_{\text{total}} = f_{L_{\text{total}}/L_{\text{w}}} L_{\text{w}} \tag{58}
\]

The standard equation for the lift of a wing is a natural monomial equality constraint:

\[
L_{\text{w}} = \frac{1}{2} \rho_{\infty} V_{\infty}^2 S_w C_{L_w} \tag{59}
\]

However, this assumes a continuous unobstructed wing planform. Correcting for lift loss at the fuselage and at the wing tips gives the adjusted Eq. (60), which can be rearranged into the posynomial constraint [Eq. (61)]:

\[
L_{\text{w}} = \frac{1}{2} \rho_{\infty} V_{\infty}^2 S_w C_{L_w} - \Delta L_{\text{w}} - 2 \Delta L_{t} \tag{60}
\]

\[
\frac{1}{2} \rho_{\infty} V_{\infty}^2 S_w C_{L_w} \geq L_{w} + \Delta L_{t} + 2 \Delta L_{t} \tag{61}
\]

The lift corrections [5] are given as monomial equality constraints:

\[
\Delta L_{t} = \eta_{\text{f}} f_{t} \frac{b_{w}}{2} p_{o} \tag{62}
\]

\[
\Delta L_{o} = f_{L} p_{\text{a}} c_{\text{root},w} \alpha_{w}^2 \tag{63}
\]
The lift coefficient of the wing goes linearly with the angle of attack, which is limited by a maximum angle of attack due to stall:

\[ C_{L_w} = C_{L_{\alpha_w}} \alpha_w \]  

\[ \alpha_w \leq \alpha_{w,\text{max}} \]  

The DATCOM formula is an analytic function for estimating the lift–curve slope of a wing or tail, based on empirical results [22]. This relationship is used as a signomial equality constraint, after some algebraic manipulation.

\[ C_{L_{\alpha_w}} = \frac{2 \pi \mathcal{R}_w}{2 + \sqrt{\left(\mathcal{R}_w/\eta_w\right)^2 (1 + \tan^2 \Lambda - M^2)} + 4} \]  

\[ \frac{C_{L_{\alpha_w}}^2}{\eta_w^2} (1 + \tan^2 \Lambda - M^2) + \frac{8 \pi C_{L_{\alpha_w}}}{\mathcal{R}_w} = 4 \pi^2 \]  

Maximum wing lift is constrained using an assumed load factor \( N_{\text{lift}} \):

\[ f_{L_{\text{total}}/L_{\text{std}}} L_{\text{max}} \geq N_{\text{lift}} W_{\text{max}} + L_{\text{max}} \]  

Finally, wing loading is constrained to be less than a user-specified maximum:

\[ W_S = \frac{1}{2} \rho_\infty C_{L_w} V_\infty^2 \]  

\[ W_S \leq W_{\text{std}} \]  

### 3. Wing Weight

Wing weight is constrained to be greater than the wing structural weight plus a series of fractional weights to account for wing ribs and control surfaces:

\[ W_{\text{wing}} \geq W_{\text{struct}} (1 + f_{\text{flap}} + f_{\text{slat}} + f_{\text{ailerons}} + f_{\text{elevators}} + f_{\text{ribs}} + f_{\text{spoilers}} + f_{\text{winds}}) \]  

The variables used to prescribe the wing box’s cross-sectional geometry are illustrated in Fig. 2.

Wing structural weight is constrained using an adaptation of the structural model from Hoburg and Abbeel [1], which comprises 12 monomial and posynomial constraints:

\[ W_{\text{struct}} \geq (W_{\text{cap}} + W_{\text{web}}) \]  

\[ W_{\text{cap}} \geq \frac{8 \rho_c g \tau_{w/c} t_{\text{cap}} s_w 1.5}{3 \mathcal{R}_w 0.5} \]  

\[ W_{\text{web}} \geq \frac{8 \rho_c g \tau_{w/c} t_{\text{web}} s_w 1.5}{3 \mathcal{R}_w 0.5} \]  

\[ \lambda^0.04 \geq 0.14 \rho_w 0.56 + 0.86 \]  

\[ p_w \geq 1 + 2 \lambda_w \]  

\[ 2q_w \geq 1 + p_w \]  

\[ \frac{0.92^2}{2} \frac{t_{w/c}}{\mathcal{R}_w} \frac{t_{\text{cap}} r_{w/c}}{t_{\text{cap}} r_{w/c}} \geq 0.92 \tau_{w/c} \frac{t_{\text{cap}} r_{w/c}}{t_{\text{cap}} r_{w/c}} + I_{\text{cap}} \]  

\[ \frac{\mathcal{R}_w M_{\text{lift}} \tau_w q_w^2}{I_{\text{cap}} s_w \sigma_{\text{max}}} \leq 8 \]  

\[ \frac{\mathcal{R}_w L_{\text{max}} N_{\text{lift}} q_w^2}{s_w \sigma_{\text{max}} \tau_{w/web}} \leq 12 \]  

\[ \mathcal{R}_w = \frac{b_w^2}{S_w} \]  

\[ \tau_w \leq 0.14 \]  

The original root bending moment constraint,

\[ M_r \geq \frac{\mathcal{R}_w L_{\text{max}} p_w}{24} \]  

is replaced with a more-sophisticated signomial constraint that considers the load relief effect due to the weight of the engine and the fuel tanks. To derive the constraint, the lift per unit span of wing is assumed to be proportional to the local chord, and the wing planform area is partitioned into an untapered (rectangular) area, \( A_{\text{rect}} \), and a fully tapered (triangular) area, \( A_{\text{tri}} \):

\[ A_{\text{rect}} = c_{\text{tip}} b_w \]  

\[ A_{\text{tri}} = \frac{1}{2} (1 - \xi_w) c_{\text{root}} b_w \]
The wing area component loads are treated as point loads to determine the equivalent wing root moment:

\[ M_r,\psi_{\text{root}} \geq \left( L_{\text{w,\max}} - N_{\text{lift}} (W_{\text{wing}} + f_{\text{fuel,wing}}W_{\text{fuel,\max}}) \right) \]

\[ \cdot \left( \frac{1}{6} A_{\text{in}} + \frac{1}{4} A_{\text{rect}} \right) b_w \cdot N_{\text{lift}} W_{\text{eng}} \frac{y_{\text{eng}}}{S_w} \]  

(86)

This constraint can be further simplified to remove the need for intermediary variables \( A_{\text{in}} \) and \( A_{\text{rect}} \) because

\[ \frac{1}{6} A_{\text{in}} + \frac{1}{4} A_{\text{rect}} = \frac{1}{12} (c_{\text{root}} - c_{\text{tip}}) b_w + \frac{1}{4} c_{\text{tip}} b_w \]  

(87)

\[ = \frac{b_w}{12} \left( c_{\text{root}} + 2 c_{\text{tip}} \right) \]  

(88)

Substituting Eq. (88) into constraint (89) yields the following wing root moment constraint:

\[ M_r,\psi_{\text{root}} \geq \left( L_{\text{w,\max}} - N_{\text{lift}} (W_{\text{wing}} + f_{\text{fuel,wing}}W_{\text{fuel,\max}}) \right) \]

\[ \cdot \frac{b_w^2}{128_w} \left( c_{\text{root}} + 2 c_{\text{tip}} \right) - N_{\text{lift}} W_{\text{eng}} \frac{y_{\text{eng}}}{S_w} \]  

(89)

Note that this provides a conservative estimate for the root moment because it assumes that the lift per unit area is constant throughout the wing, whereas in reality the lift per unit area diminishes toward the wing tips.

4. Wing Drag

Wing drag is captured by five monomial and posynomial constraints. The parasitic drag coefficient is constrained using a softmax affine fit of XFOIL [24] simulation data for the TASOPT [5] C-series airfoils, which are representative of modern transonic airfoils [5]. The fit, which considers wing thickness, lift coefficient, Reynolds number, and Mach number, was developed with GPfit [10,25] and has an rms error of approximately 5%. Constraint (97) is an adaption of the standard definition of the induced drag coefficient [17], with an adjustment factor for wing-tip devices:

\[ D_{w} = \frac{1}{2} \rho_{\infty} V_{\infty}^2 S_w C_{D_w} \]  

(90)

\[ C_{D_{w}} \geq C_{D_{w,\text{root}}} + C_{D_{w,\text{fueltotal}}} \]  

(91)

\[ C_{D_{w,\text{root}}} \geq 1.61 \left( \frac{R_{\infty}}{1000} \right)^{-0.550} (\tau_w)^{1.29} (M \cos(A))^{0.04} C_{L_w}^{1.78} \]

\[ + 0.0466 \left( \frac{R_{\infty}}{1000} \right)^{-0.389} (\tau_w)^{0.84} (M \cos(A))^{-0.340} C_{L_w}^{0.951} \]

\[ + 191 \left( \frac{R_{\infty}}{1000} \right)^{-0.219} (\tau_w)^{3.95} (M \cos(A))^{-0.340} C_{L_w}^{1.15} \]

\[ + 2.82 e - 12 \left( \frac{R_{\infty}}{1000} \right)^{1.18} (\tau_w)^{-1.76} (M \cos(A))^{0.105} C_{L_w}^{1.44} \]  

(92)

\[ Re_w = \frac{\rho_{\infty} V_{\infty} c_w}{\mu} \]  

(93)

\[ C_{D_{w}} \geq 0.0135 \frac{C_{L_w}^{2}}{\tau_w} \]  

(94)

The Oswald efficiency is constrained by a relationship from [26], in which the authors fit a polynomial function to empirical data. Given that all polynomials are signomials, this can easily be used in the SP framework:

\[ e \leq \frac{1}{1 + f(\lambda_w) R_{\infty}} \]  

(95)

\[ f(\lambda_w) \geq 0.0524\lambda_w^4 - 0.15\lambda_w^3 + 0.1659\lambda_w^2 - 0.0706\lambda_w + 0.0119 \]  

(96)

The Oswald efficiency is plotted as a function of taper ratio, as imposed by this pair of constraints, in Fig. 3.

5. Wing Aerodynamic Center

The wing’s true aerodynamic center and c.g. are shifted back with respect to its root quarter-chord, due to its sweep. Assuming that the lift per unit area is constant, the magnitude of this shift can be calculated by integrating the product of the local quarter chord offset, \( \delta x(\gamma) \), and local chord, \( c(\gamma) \), over the wing half-span:

\[ \Delta x_{w,\text{root}} = \frac{2}{S} \int_{0}^{b/2} c(\gamma) \delta x(\gamma) \, d\gamma \]  

(97)

\[ c(\gamma) = \left( 1 - (1 - \lambda_w) \frac{2\gamma}{b_w} \right) c_{\text{root}} \]  

(98)

\[ \delta x(\gamma) = y \tan(A) \]  

(99)

By substituting Eqs. (98) and (99) into Eq. (97), expanding out the integral, and relaxing the equality, \( \Delta x_{w,\text{root}} \) can be constrained as follows:

\[ \Delta x_{w,\text{root}} \leq \frac{1}{4} \tan(A) R_{\infty} c_{\text{root}} \left( \frac{1}{3} + \frac{2}{3} \frac{\lambda_w}{\mu} \right) \]  

(100)

6. Fuel Volume

Fuel tanks are typically located inside the wing box. Using the geometry of a TASOPT-optimized 737-800 [5], a constraint on the maximum fuel volume in the wing was developed. For a wing of the same mean aerodynamic chord, thickness, and span as a TASOPT 737-800, the maximum available fuel volumes in the wing will match exactly. To allow for the possibility of auxiliary tanks in the
1. Vertical Tail Geometry and Structure

B. Model Description

A. Model Assumptions

For a multi-engine aircraft, the critical flight condition is typically an engine failure at low speeds. The vertical tail must be capable of providing sufficient side force in this case [27]. The vertical tail must also provide adequate yaw rate acceleration during landing flare in crosswind conditions. The design of the vertical tail is therefore coupled to the size of the fuselage, the position of the engines, and the aircraft’s moment of inertia.

A. Model Assumptions

The high-level assumptions for this model are that the horizontal tail is mounted on the fuselage, so as not to require a reinforced vertical tail structure, and that the aircraft has two engines.

B. Model Description

The vertical tail model has 42 free variables and 31 constraints. Tables 5 and 6 list the free and fixed variables that appear in constraints that are unique to the vertical tail model.

IV. Vertical Tail Model

At a conceptual design level, the purpose of an aircraft’s vertical tail is twofold. First, it must provide stability in yaw. Second, it must provide adequate yaw control authority in critical flight conditions. For a multi-engine aircraft, the critical flight condition is typically an engine failure at low speeds. The vertical tail must be capable of providing sufficient side force in this case [27]. The vertical tail must also provide adequate yaw rate acceleration during landing flare in crosswind conditions. The design of the vertical tail is therefore coupled to the size of the fuselage, the position of the engines, and the aircraft’s moment of inertia.

A. Model Assumptions

The high-level assumptions for this model are that the horizontal tail is mounted on the fuselage, so as not to require a reinforced vertical tail structure, and that the aircraft has two engines.

B. Model Description

The vertical tail model has 42 free variables and 31 constraints. Tables 5 and 6 list the free and fixed variables that appear in constraints that are unique to the vertical tail model.

1. Vertical Tail Geometry and Structure

The variables that define geometry are illustrated in Fig. 4. The moment arm of the vertical tail is the distance from the aircraft c.g. to the aerodynamic center of the vertical tail, which is assumed to be at the quarter-chord. The moment arm is therefore upper-bounded by the distance from the c.g. to the leading edge of the tail at the root, the height of the mean aerodynamic chord above the fuselage, the sweep angle, and the mean aerodynamic chord:

\[ l_{vt} \leq \Delta x_{lead,vt} + z_{vt} \tan(\alpha_{vt}) + 0.25 \bar{c}_{vt} \]

The \( x \) coordinates of the leading and trailing edge at the root are related by the root chord. The tail trailing edge is upper-bounded by imposing a constraint that the tail root cannot extend beyond the end of the fuselage. Together, these constraints put an upper bound on the moment arm of the tail based on the length of the fuselage:

\[ \Delta x_{trail,vt} \geq \Delta x_{lead,vt} + \bar{c}_{root,vt} \]

The location of the vertical tail c.g. is also constrained approximately using simple geometry:

\[ x_{CG,vt} \geq x_{CG} + \frac{1}{2} (\Delta x_{lead,vt} + \Delta x_{trail,vt}) \]
The vertical tail structure is sized by its maximum lift coefficient and the never-exceed speed:

\[ L_{\text{v,\text{max}}} \geq \frac{1}{2} \rho_{\infty} V_{\infty}^2 S_{\text{v}} C_{L_{\text{v,\text{max}}}} \]  

(108)

The remaining geometry and structural constraints were already introduced in the wing model. Constraints (51–55) are adapted to the vertical tail model to constrain its geometry, with two minor modifications. Constraint (51) can be relaxed from a signomial equality constraint, whereas constraint (52) needs to be implemented as a signomial equality constraint. The vertical wing structure model from [1] is also reused; however, given that the vertical tail only has a half-span, the definitions of \( b_{\text{vt}}, S_{\text{v}}, \) and \( W_{\text{vt}} \) differ accordingly from those of their wing counterparts.

2. Engine-Out Condition

The first performance constraint specifies that the maximum moment exerted by the tail must be greater than or equal to the moment exerted by the engines in an engine-out condition, exacerbated by the windmill drag of the engine that is inoperative [5]:

\[ L_{\text{vt,EO}} \geq D_{\text{wm,Eng}} + T_{\text{TO}} Y_{\text{Eng}} \]  

(109)

The worst-case engine-out condition is likely to occur during takeoff, when the velocity is lowest but the engine force required to safely complete takeoff is highest. The force exerted by the vertical tail in this critical low speed case is constrained by its maximum lift coefficient, its reference area, and the minimum dynamic pressure. As a conservative estimate, the \( V_J \) speed is used because it is the minimum speed after which a takeoff can be completed, following a critical engine failure:

\[ L_{\text{vt,EO}} = \frac{1}{2} \rho_{\text{T}} V_{\text{J}}^2 S_{\text{v}} C_{L_{\text{vt,EO}}} \]  

(110)

The wing lift coefficient is constrained by the airfoil sectional lift coefficient using finite wing theory [28]:

\[ C_{L_{\text{v,EO}}} \left( 1 + \frac{\epsilon_{\text{L,EO}}}{\pi \rho_{\text{v}} A_{\text{v,EO}}} \right) \leq C_{\text{L,EO}} \]  

(111)

The windmill drag can, to a first approximation, be lower-bounded using a drag coefficient and a reference area [5], in this case the area of the engine fan:

\[ D_{\text{wm}} \geq \frac{1}{2} \rho_{\text{T}} V_{\text{T}}^2 A_{\text{fan}} C_{D_{\text{wm}}} \]  

(112)

3. Crosswind Landing Condition

The second performance constraint ensures the vertical tail can provide adequate yaw rate acceleration in a crosswind landing, where the moment of inertia was constrained at the system level (Sec. II). To provide a safety margin during cross-wind landing, \( C_{L_{\text{v,\text{cross}}} \text{ Winds}} \) is taken to be 85% of \( C_{L_{\text{v,\text{EO}}} \text{ Winds}} \):

\[ \frac{1}{2} \rho_{\text{T}} V_{\text{wind}}^2 S_{\text{v}} \frac{L_{\text{vt,\text{wind}}}}{L_{\text{vt,\text{EO}}} \text{ Winds}} \geq \frac{\dot{\tau}_{\text{EO}}}{I_{\text{e}}} \]  

(113)

4. Vertical Tail Drag

The vertical tail produces drag, regardless of the flight condition. Neglecting any induced drag, the parasitic drag coefficient \( C_{D_{\text{v}}} \) is set by a softmax affine fit of XFOIL [24] data for the symmetric NACA 0008 through 0020 airfoils. The fit considers airfoil thickness, Mach number, and Reynolds number. It was developed with GPfit [10, 25] and has an rss error of 1.31%:

\[ D_{\text{v}} \geq \frac{1}{2} \rho_{\infty} V_{\infty}^2 S_{\text{v}} C_{D_{\text{v}}} \]  

(114)

\[ C_{D_{\text{v}}} \geq 2.44 \times 10^{-7} (R_{\text{e}})_{-0.528} (\tau_{\text{EO}}^{133.3}) (M)^{-122.7} + 0.003 (R_{\text{e}})_{-0.410} (\tau_{\text{EO}})^{1.22} (M)^{0.55} + 1.967 \times 10^{-4} (R_{\text{e}})_{-0.214} (\tau_{\text{EO}})^{0.04} (M)^{-0.14} + 6.590 \times 10^{-5} (R_{\text{e}})_{-0.498} (\tau_{\text{EO}})^{1.56} (M)^{-114.6} \]  

(115)

\[ R_{\text{e}} = \frac{\rho_{\infty} V_{\infty} \bar{C}_{\text{D,EO}}}{\mu} \]  

(116)

V. Horizontal Tail Model

At a conceptual design level, the purpose of the horizontal tail is threefold: to trim the aircraft such that it can fly in steady level flight, to provide longitudinal stability, and to give the pilot pitch control authority over a range of flight conditions.

A. Model Assumptions

The horizontal tail model assumes that the horizontal stabilizer is mounted to the fuselage and nominally produces downforce in cruise.

B. Model Description

The horizontal tail model has 50 free variables and 33 constraints. Tables 7 and 8 list the free and fixed variables that appear in constraints that are unique to the horizontal tail model.

1. Horizontal Tail Geometry and Structure

The horizontal tail model employs many of the same geometric constraints as the wing and vertical tail. More specifically, analogous versions of constraints (51–55) and constraints (107–110) enforce planform relationships and constrain the horizontal tail moment arm, respectively. As with the vertical tail, constraint (52) needs to be implemented as a signomial equality constraint. The horizontal tail also reuses the same structural model from [1]. The variables that define geometry are illustrated in Fig. 5.

| Table 7 Free variables from constraints that are unique to the horizontal tail model (HT, horizontal tail) |

| \( CL_{\text{ht,max}} \) | ——              | Maximum horizontal tail lift coefficient |
| \( CL_{\text{ht,max}} \) | ——              | Maximum lift coefficient, wing |
| \( C_{\text{ht,e}} \) | ——              | Moment coefficient about aerodynamic center (wing) |
| \( SM_{\text{min}} \) | m               | Minimum allowed stability margin |
| \( \Delta M_{\text{CG ht}} \) | m               | Center of gravity travel range |
| \( \eta_{\text{ht}} \) | ——              | Tail efficiency |
The ratio of the horizontal tail and wing lift–curve slopes, $m_{\text{ratio}}$, appears in Eq. (123) and is constrained using the relationship in [29]. The constraint is a signomial equality because it is not possible to know a priori whether there will be upward or downward pressure on $m_{\text{ratio}}$:

$$m_{\text{ratio}} \left(1 + \frac{2}{Re_w} \right) = 1 + \frac{2}{Re_{ht}}$$  \hfill (124)$$

4. Stability Margin
The third condition is that the stability margin must be greater than a minimum specified value for all intermediate c.g. locations:

$$SM \leq \frac{x_w - x_{CG}}{c_w}$$  \hfill (125)$$

$$SM \geq SM_{\text{min}}$$  \hfill (126)$$

5. Horizontal Tail Drag
The horizontal tail employs the same drag model as the wing [constraints (93–97)], with the exception of the parasitic drag coefficient fit. The wing’s parasitic drag fit [Eq. (92)] is replaced by a fit to XFOIL [24] data for the TASOPT [5] T-series airfoils. The TASOPT T-series airfoils are horizontal tail airfoils intended for transonic use. The fit considers airfoil thickness, Reynolds number, and Mach number. The softmax affine function fit is developed with GPfit [10,25] and has an rms error of 1.14%:

$$C_{\text{D}_{ht}} \geq C_{\text{D}_{ht}}^{\text{fit}} \left[1.676 \times 10^{-28} \left(Re_{ht}\right)^{0.351} \left(t_{ht}\right)^{0.812} \left(M\right)^{10.256} + 7.098 \times 10^{-25} \left(Re_{ht}\right)^{1.395} \left(t_{ht}\right)^{1.962} \left(M\right)^{0.567} + 4.313 \times 10^{-14} \left(Re_{ht}\right)^{-2.574} \left(t_{ht}\right)^{1.128} \left(M\right)^{0.448} + 1.443 \times 10^{-12} \left(Re_{ht}\right)^{-3.910} \left(t_{ht}\right)^{4.660} \left(M\right)^{7.689}$$  \hfill (127)$$

VI. Fuselage Model
At a high level, the purpose of a conventional commercial aircraft fuselage can be decomposed into two primary functions: integrating and connecting all of the subsystems (e.g., wing, tail, landing gear) and carrying the payload, which typically consists of passengers, luggage, and sometimes cargo. The design of the fuselage is therefore coupled with virtually every aircraft subsystem.

Drela [5] performs a detailed analysis of fuselage structure and weight, considering pressure loads, torsion loads, bending loads, buoyancy weight, window weight, payload-proportional weights, the floor, and the tail cone. The majority of the constraints in this model are adapted directly from these equations.

A. Model Assumptions
This model assumes a single circular-cross-section fuselage. The floor structural model and the horizontal bending model assume uniform floor loading. The model leverages the analytical bending models from Drela [5], which makes assumptions about symmetry in bending loads. Shell buckling is not explicitly modeled while designing bending structure but is accounted for by the implementation of a lower yield stress for bending reinforcement material relative to the nominal yield stress of the material.

B. Model Description
The fuselage model has 84 free variables and 96 constraints. Tables 9 and 10 list the model’s free and fixed variables, respectively.

</tbody>
</table>
1. Cross-Sectional Geometry

The variables that define geometry are illustrated in Figs. 6 and 7. The fuselage must be wide enough to accommodate the width of the seats in a row and the width of the aisle:

\[ w_{\text{fuse}} \geq n_{\text{spr}} w_{\text{seat}} + w_{\text{aisle}} + 2w_{\text{sys}} \]  \hspace{1cm} (128)

The cross-sectional area of the fuselage skin is lower-bounded using a thin-walled cylinder assumption:

\[ A_{\text{skin}} \geq 2 \pi R_{\text{fuse}} t_{\text{skin}} \]  \hspace{1cm} (129)

The cross-sectional area of the fuselage is lower-bounded using the radius of the fuselage:

\[ A_{\text{fuse}} \geq \pi R_{\text{fuse}}^2 \]  \hspace{1cm} (130)

2. Pressure Loading

The axial and hoop stresses in the fuselage skin are constrained by the pressurization load due to the difference between cabin pressure and ambient pressure at cruise altitude. The thickness of the skin is therefore sized by the maximum allowable stress of the chosen material:

\[ \sigma_x = \frac{\Delta P_{\text{over}} R_{\text{fuse}}}{2 t_{\text{shell}}} \]  \hspace{1cm} (131)

\[ \sigma_\theta = \frac{\Delta P_{\text{over}} R_{\text{fuse}}}{t_{\text{skin}}} \]  \hspace{1cm} (132)

3. Floor Loading

The floor must be designed to withstand at least the weight of the payload and seats multiplied by a safety factor for an emergency landing:

\[ P_{\text{floor}} \geq N_{\text{land}} (W_{\text{pay}} + W_{\text{seats}}) \]  \hspace{1cm} (135)

The maximum moment and shear in the floor are determined based on this design load and the width of the floor, assuming that the floor/wall joints are pinned and there are no center supports:

\[ S_{\text{floor}} = \frac{P_{\text{floor}}}{2} \]  \hspace{1cm} (136)

\[ M_{\text{floor}} = \frac{P_{\text{floor}} w_{\text{floor}}}{8} \]  \hspace{1cm} (137)

The floor beam cross-sectional area is constrained by the maximum allowable cap stress and shear web stress for the beams:

\[ A_{\text{floor}} \geq 1.5 S_{\text{floor}} \frac{\tau_{\text{floor}}}{\sigma_{\text{floor}} h_{\text{floor}}} \]  \hspace{1cm} (138)

4. Shell Geometry

The cylindrical shell of the fuselage sits between the nose and tailcone. The variables \(x_{\text{shell1}}\) and \(x_{\text{shell2}}\) define the beginning and end of the cylindrical section of the fuselage, respectively, in the aircraft \(x\) axis:

\[ x_{\text{shell1}} = l_{\text{nose}} \]  \hspace{1cm} (139)

\[ x_{\text{shell2}} \geq l_{\text{nose}} + l_{\text{shell}} \]  \hspace{1cm} (140)

The number of seats is equal to the product of the seats per row and the number of rows. Note that noninteger numbers of rows are allowed and necessary for GP compatibility. It is assumed that the load factor is 1, so that the number of passengers is equal to the number of seats:

\[ n_{\text{pass}} = n_{\text{seat}} \]  \hspace{1cm} (142)

The seat pitch and the number of rows of seats constrain the length of the shell. The floor length is lower-bounded by the shell length and twice the fuselage radius, to account for the space provided by pressure bulkheads:

\[ l_{\text{shell}} \geq n_{\text{rows}} p_s \]  \hspace{1cm} (143)

\[ l_{\text{floor}} \geq 2R_{\text{fuse}} + l_{\text{shell}} \]  \hspace{1cm} (144)

The length of the fuselage is constrained by the sum of the nose, shell, and tail cone lengths. A signomial equality is needed because increased fuselage length results in improved tail control authority:

\[ l_{\text{fuse}} = l_{\text{nose}} + l_{\text{shell}} + l_{\text{cone}} \]  \hspace{1cm} (145)

Other locations to constrain are the wing midchord and the wingbox fore and aft bulkheads, which serve as integration limits when calculating bending loads:
The skin surface area and, in turn, skin volume for the nose, main cabin, and rear bulkhead are constrained. The surface area of the nose, which is approximated as an ellipse, is lower-bounded using Cantrell’s approximation [5]:

\[ s_{nose}^{h/5} \geq (2\pi R_{\text{fuselage}}^{h/5})(1 + \frac{2}{3} \frac{l_{\text{nose}}}{R_{\text{fuselage}}}) \]  

(148)

\[ S_{\text{bulk}} = 2\pi R_{\text{fuselage}}^2 \]  

(149)

\[ V_{\text{cyl}} = A_{\text{skin}} l_{\text{shell}} \]  

(150)

\[ V_{\text{nose}} = S_{\text{nose}} t_{\text{skin}} \]  

(151)

\[ V_{\text{bulk}} = S_{\text{bulk}} t_{\text{skin}} \]  

(152)

The cabin volume, necessary for capturing buoyancy weight, is constrained assuming a cylinder with hemispherical end caps:

\[ V_{\text{cabin}} \geq A_{\text{fuselage}} \left( \frac{2}{3} l_{\text{nose}} + l_{\text{shell}} + \frac{2}{3} R_{\text{fuselage}} \right) \]  

(153)

5. Tail Cone

The tail cone needs to be able to transfer the loads exerted on the vertical tail to the rest of the fuselage. The maximum torsion moment imparted by the vertical tail, \( Q_{\text{vt}} \), depends on the maximum force exerted on the tail as well as its span and taper ratio, \( \lambda_{\text{vt}} \). This torsion moment, along with the cone cross-sectional area and the maximum shear stress of the cone material, bounds the necessary cone skin thickness. The cone cross-sectional area, which varies along the cone, is coarsely approximated to be the fuselage cross-sectional area (i.e., the cross-sectional area of the cone base):

\[ Q_{\text{vt}} = \frac{L_{\text{max}} b_{\text{vt}}}{3} \left( 1 + \frac{2\lambda_{\text{vt}}}{1 + \lambda_{\text{vt}}} \right) \]  

(154)

\[ t_{\text{cone}} = \frac{Q_{\text{vt}}}{2A_{\text{fuselage}} t_{\text{cone}}} \]  

(155)

The volume of the cone is a definite integral from the base to the tip of the cone. This integral is evaluated [5] and combined with Eqs. (154) and (155) to give a single signomial constraint on the cone skin volume:

\[ R_{\text{fuselage}} t_{\text{cone}} (1 + p_{\text{vt}}) V_{\text{cone}}^{1 + \lambda_{\text{cone}}/4} \geq L_{\text{max}} b_{\text{vt}} \frac{p_{\text{vt}}}{3} \]  

(156)

6. Fuselage Area Moment of Inertia

The fuselage shell consists of the skin and stringers. Its area moment of inertia determines how effectively the fuselage is able to resist bending loads. A shell with uniform skin thickness and stringer density has a constant area moment of inertia in both of its bending axes.

To be consistent with [5], the horizontal bending moments are defined as the moments around the aircraft’s \( y \) axis, caused by horizontal tail loads and fuselage inertial loads, and vertical bending moments are defined as the moments around the aircraft’s \( z \) axis, caused by vertical tail loads.

The effective modulus-weight shell thickness is lower-bounded by assuming that only the skin and stringers contribute to bending. This constraint also uses an assumed fractional weight of stringers that scales with the thickness of the skin:

\[ t_{\text{shell}} \geq t_{\text{skin}} \left( 1 + f_{\text{string}} \frac{\rho_{\text{skin}}}{\rho_{\text{bend}}} \right) \]  

(159)

It is important to consider the effects of pressurization on the yield strength of the bending material. Because pressurization stresses the airframe, the actual yield strength of the fuselage bending material is lower than its nominal yield strength, an effect captured using posynomial constraints:

\[ \sigma_{M_{\text{h}}} + r_{\text{E}} \frac{\Delta P_{\text{over}}}{t_{\text{shell}}} \leq \sigma_{\text{bend}} \]  

(160)

\[ \sigma_{M_{\text{l}}} + r_{\text{E}} \frac{\Delta P_{\text{over}}}{t_{\text{shell}}} \leq \sigma_{\text{bend}} \]  

(161)

The aircraft shell, which is composed of the pressurized skin and stringers, must satisfy the following horizontal and vertical area moment of inertia constraints:

\[ I_{\text{hshell}} \leq \pi R_{\text{fuselage}}^3 t_{\text{shell}} \]  

(162)

\[ I_{\text{vshell}} \leq \pi R_{\text{fuselage}}^3 t_{\text{shell}} \]  

(163)

7. Horizontal Bending Model

There are two load cases that determine the required horizontal bending material (HBM): maximum load factor (MLF) at \( V_{\text{ref}} \), where

\[ N = N_{\text{lift}} \]  

(164)

\[ L_{\text{ht}} = L_{\text{mpmax}} \]  

(165)

and emergency landing impact, where

\[ N = N_{\text{land}} \]  

(166)

\[ L_{\text{ht}} = 0 \]  

(167)

Both load cases are considered at the aircraft’s maximum takeoff weight. The constraints for each case are distinguished by the subscripts “MLF” and “land”. Assuming that the fuselage weight is uniformly distributed throughout the shell, the bending loads due to fuselage inertial loads increase quadratically from the ends of the fuselage shell to the aircraft c.g., as shown by the line representing \( M_{\text{f}}(x) \) in Fig. 8. The tail loads are point loads at \( x_{\text{tail}} \), so the horizontal tail moment increases linearly from \( x_{\text{tail}} \) to the aircraft’s c.g. In the maximum load factor case, the maximum moment exerted by the horizontal tail is superimposed on the maximum fuselage inertial moment at load factor \( N_{\text{lift}} \) to size the HBM required. For the emergency landing impact case, only the fuselage inertial loads are considered at \( N_{\text{land}} \), assuming an unloaded horizontal tail.
Several intermediate variables are introduced and used in constraints that capture HBM relationships. $A_{\text{sh}}$ represents the HBM area that is contributed by the aircraft shell:

$$A_{\text{sh}} = \frac{I_{\text{shell}}}{r_p h_{\text{fuse}}^2}$$  \hspace{1cm} (168)

Variables $A_{\text{h,land}}$ and $A_{\text{h,land}}$ are the HBM lengths that are required to sustain bending loads from the tail. Note that as the distance from the tail increases, the moment exerted from the tail increases linearly:

$$A_{\text{h,land}} \geq \frac{N_{\text{Land}}}{h_{\text{fuse}} \sigma_{\text{L}}} (W_{\text{ct}} + W_{\text{ht}} + W_{\text{apu}})$$ \hspace{1cm} (169)

$$A_{\text{h,land}} \geq \frac{N_{\text{Land}}}{h_{\text{fuse}} \sigma_{\text{L}}} (W_{\text{ct}} + W_{\text{ht}} + W_{\text{apu}})$$ \hspace{1cm} (170)

Variables $A_{\text{h,wing}}$ and $A_{\text{h,wing}}$ represent the HBM required to sustain the distributed loads in the fuselage. As the distance from the nose or the tail increases, the moment exerted due to the distributed load grows with the square of length:

$$A_{\text{h,wing}} \geq \frac{N_{\text{Land}}}{2 h_{\text{fuse}} \sigma_{\text{M}}} (W_{\text{pay}} + W_{\text{padd}} + W_{\text{shell}} + W_{\text{window}} + W_{\text{floor}} + W_{\text{seats}})$$ \hspace{1cm} (171)

$$A_{\text{h,wing}} \geq \frac{N_{\text{Land}}}{2 h_{\text{fuse}} \sigma_{\text{M}}} (W_{\text{pay}} + W_{\text{padd}} + W_{\text{shell}} + W_{\text{window}} + W_{\text{floor}} + W_{\text{seats}})$$ \hspace{1cm} (172)

Bending reinforcement material in the aircraft exists where the shell inertia is insufficient to sustain the local bending moment. Constraints are used to determine the location over the rear fuselage $x_{\text{bend}}$, forward of which additional HBM is required. Some simple constraints on geometry are added to ensure a meaningful solution. Constraints (173–180) apply for both load cases in the model (with subscript $c$ replaced by “MLF” or “land”):

$$A_{\text{sh}} = A_{\text{sh}} (x_{\text{shell}} - x_{\text{bend}}^2) + A_{\text{h}} (x_{\text{tail}} - x_{\text{bend}})$$ \hspace{1cm} (173)

$$x_{\text{bend}} \geq x_{\text{wing}}$$ \hspace{1cm} (174)

To be able to constrain the volume of HBM required, the area of HBM required must be constrained and integrated over the length of the fuselage. As shown by [5], with some conservative approximation, the volume of HBM may be determined through the integration of the forward and rear wing box HBM areas over the rear fuselage:

$$V_{\text{h}} \geq A_{\text{h,shell}} (x_{\text{shell}} - x_{\text{f}})^2 + A_{\text{h}} (x_{\text{tail}} - x_{\text{f}}) - A_{\text{sh}}$$ \hspace{1cm} (176)

$$V_{\text{h}} \geq A_{\text{h,shell}} (x_{\text{shell}} - x_{\text{f}})^2 + A_{\text{h}} (x_{\text{tail}} - x_{\text{f}}) - A_{\text{sh}}$$ \hspace{1cm} (177)

HBM volumes forward, over, and behind the wing box are lower-bounded by the integration of the HBM areas over the three fuselage sections:

$$V_{\text{h}} \geq \frac{A_{\text{h,shell}}}{3} (x_{\text{shell}} - x_{\text{f}})^3 - (x_{\text{shell}} - x_{\text{bend}})^3$$

$$+ \frac{A_{\text{h}}}{2} (x_{\text{tail}} - x_{\text{f}})^2 - (x_{\text{tail}} - x_{\text{bend}})^2$$

$$- A_{\text{sh}} (x_{\text{bend}} - x_{\text{f}})$$ \hspace{1cm} (178)

$$V_{\text{h}} \geq \frac{A_{\text{h,shell}}}{3} (x_{\text{shell}} - x_{\text{f}})^3 - (x_{\text{shell}} - x_{\text{bend}})^3$$

$$+ \frac{A_{\text{h}}}{2} (x_{\text{tail}} - x_{\text{f}})^2 - (x_{\text{tail}} - x_{\text{bend}})^2$$

$$- A_{\text{sh}} (x_{\text{bend}} - x_{\text{f}})$$ \hspace{1cm} (179)

$$V_{\text{h}} \geq 0.5 (A_{\text{h,shell}} + A_{\text{h,shell}}) C_{\text{L}}$$ \hspace{1cm} (180)

The total HBM volume is lower-bounded by the sum of the volumes of HBM required in each fuselage section:

$$V_{\text{h}} \geq V_{\text{h,shell}} + V_{\text{h,shell}} + V_{\text{h,shell}}$$ \hspace{1cm} (181)

8. Vertical Bending Model

The vertical bending material (VBM) is constrained by considering the maximum vertical tail loads that a fuselage must sustain. The vertical bending moment, shown as $M_v(x)$ in Fig. 8,
increases linearly from the tail to the aircraft c.g. because the tail lift is assumed to be a point force.

As with horizontal bending, several intermediate variables are introduced and used in constraints that capture VBM relationships, $B_{1v}$ is the VBM length required to sustain the maximum vertical tail load $L_{t_{尾}}$. When multiplied by the moment arm of the tail relative to the fuselage cross-sectional location, it gives the local VBM area required to sustain the loads:

$$B_{1v} = \frac{r_{M}L_{t_{尾}}}{R_{尾}r_{M}} \sigma_{M}$$

(182)

$B_{0v}$ is the equivalent VBM area provided by the fuselage shell:

$$B_{0v} = \frac{I_{壳}}{r_{壳}R_{尾}^2}$$

(183)

$x_{bend}$ is the location where the vertical bending moment of the inertia of the fuselage is exactly enough to sustain the maximum vertical bending loads from the tail, expressed by a signomial equality:

$$B_{0v} = B_{1v}(x_{t_{尾}} - x_{bend})$$

(184)

$$x_{bend} \geq x_{wing}$$

(185)

$$x_{bend} \leq l_{fuse}$$

(186)

Behind this point, no additional VBM is required.

The VBM area required at the rear of the wing box is lower-bounded by the tail bending moment area minus the shell vertical bending moment area:

$$A_{bend} \geq B_{1v}(x_{t_{尾}} - x_{b}) - B_{0v}$$

(187)

The vertical bending volume aft of the wing box is then constrained by integrating $A_{bend}$ over the rear fuselage, which yields the following constraint:

$$V_{bend} \geq 0.5B_{1v}((x_{t_{尾}} - x_{b})^2 - (x_{tail} - x_{bend})^2) - B_{0v}(x_{bend} - x_{b})$$

(188)

The vertical bending volume over the wing box is the average of the bending area required in the front and back of the wing box. Because no vertical bending reinforcement is required in the forward fuselage, the resulting constraint is simply:

$$V_{bend} \geq 0.5A_{bend}c_{f_{尾}}w_{c}$$

(189)

The total vertical bending reinforcement volume is the sum of the volumes over the wing box and the rear fuselage:

$$V_{bend} \geq V_{bend} + V_{bend}$$

(190)

**9. Fuselage Weight**

The total weight of the fuselage is lower-bounded by the sum of all of the constituent weights:

$$W_{fuse} \geq W_{apu} + W_{cone} + W_{floor} + W_{bend} + W_{inertial} + W_{padd} + W_{seats} + W_{shell} + W_{window} + W_{fix}$$

(191)

The weight of the fuselage skin is the product of the skin volumes (bulkhead, cylindrical shell, and nosecone) and the skin density:

$$W_{skin} \geq \rho_{skin}(V_{bulk} + V_{cyl} + V_{nose})$$

(192)

The weight of the fuselage shell is then constrained by accounting for the weights of the frame, stringers, and other structural components, all of which are assumed to scale with the weight of the skin:

$$W_{shell} \geq W_{skin}(1 + f_{fadd} + f_{frame} + f_{string})$$

(193)

The weight of the floor is lower-bounded by the density of the floor beams multiplied by the floor beam volume, in addition to an assumed weight/area density for planking:

$$W_{floor} \geq \rho_{floor}V_{floor}$$

(194)

$$W_{floor} \geq V_{floor}l_{floor}g + W_{floor}l_{floor}w_{floor}$$

(195)

As with the shell, the tail cone weight is bounded using assumed proportional weights for additional structural elements, stringers, and frames:

$$W_{cone} \geq \rho_{cone}gV_{cone}(1 + f_{fadd} + f_{frame} + f_{string})$$

(196)

The weight of the horizontal/vertical bending material is a product of the bending material density and the HBM/VBM volume required

$$W_{bend} \geq \rho_{bend}V_{bend}$$

(197)

$$W_{bend} \geq \rho_{bend}V_{bend}$$

(198)

The window and insulation weights are lower-bounded using assumed weight-per-length and weight-per-area densities, respectively. It is assumed that only the passenger compartment of the cabin is insulated and that the passenger compartment cross-sectional area is approximately 55% of the fuselage cross-sectional area:

$$W_{window} = W_{window}l_{shell}$$

(199)

$$W_{inertial} \geq W_{inertial}(0.55(S_{fuse} + S_{nose}) + 1.1R_{fuse}l_{shell})$$

(200)

The auxiliary power unit (APU) and other payload proportional weights are accounted for using weight fractions. $W_{payload}$ includes flight attendants, food, galleys, toilets, furnishing, doors, lighting, air conditioning, and in-flight entertainment systems. The total seat weight is a product of the weight per seat and the number of seats:

$$W_{apu} = W_{payf_{apu}}$$

(201)

$$W_{padd} = W_{payf_{padd}}$$

(202)

$$W_{seats} = W_{seat}n_{seats}$$

(203)

The effective buoyancy weight of the aircraft is constrained using a specified cabin pressure $\rho_{cabin}$, the ideal gas law, and the approximated cabin volume. A conservative approximation for the buoyancy weight that does not subtract the ambient air density from the cabin air density is used:

$$\rho_{cabin} = \frac{p_{cabin}}{RT_{cabin}}$$

(204)

$$W_{buoy} = \rho_{cabin}gV_{cabin}$$

(205)

The fixed weight $W_{fix}$ incorporates pilots, cockpit windows, cockpit seats, flight instrumentation, and navigation and communication equipment, which are expected to be roughly the same for all aircraft [5]. The payload weight is bounded using an average weight per passenger, which includes luggage:

$$W_{pay} \geq W_{avg}_{pass}n_{pass}$$

(206)
10. Fuselage Drag

The drag of the fuselage is constrained using $C_{D_{fuse}}$ from TASOPT, which calculates the drag using a pseudoaxisymmetric viscous/inviscid calculation, and scaling appropriately by fuselage dimensions and Mach number:

$$D_{fuse} = \frac{1}{2} \rho_{\infty} V_{\infty}^2 C_{D_{fuse}} \left( t_{fuse} R_{fuse} \frac{M^2}{M_{\text{fuel}}^2} \right)$$ (207)

VII. Landing-Gear Model

The purpose of the landing gear is to support the weight of the aircraft and allow it to maneuver while it is on the ground, including during taxi, takeoff, and landing. Including the landing gear in aircraft MDO is important, not only because it typically weighs between 3 and 6% of the maximum aircraft takeoff weight [30], but also because of how coupled its design is to other subsystems, particularly the fuselage, wings, and engines. The landing-gear geometry is constrained by wing position, engine clearance, takeoff rotation, and tip-over criteria. In addition to being able to withstand nominal static and dynamic loads, the landing gear also needs to be able to absorb touchdown shock loads. These loads and the required geometry determine the weight of the gear. Many of the constraints imposed on landing-gear design are described in [30,31].

A. Model Assumptions

The landing-gear model assumes a conventional and retractable tricycle landing-gear configuration for narrowbody commercial aircraft such as a Boeing 737-800. The nose gear consists of a single strut supported by two wheels. The main gear consists of two struts mounted in the inboard section of the wings, each supported by two wheels. The model only takes one c.g. location as an input (i.e., it does not consider c.g. travel). It is also assumed that the main landing gear retracts toward the centerline of the aircraft, rotating about the x axis.

B. Model Description

The landing-gear model has 46 free variables and 54 constraints. Tables 11 and 12 list the model’s free and fixed variables, respectively. The variables that define geometry are illustrated in Fig. 9.

1. Landing-Gear Position

The landing-gear track and base are defined relative to the $x$ and $y$ coordinates of the nose and main gear:

$$T = 2 y_m$$ (208)

$$x_m \geq x_n + B$$ (209)

The geometric relationships between the $x$ coordinates of the main gear, nose gear, and the c.g. position must be enforced. These relationships are:

$$x_n + \Delta x_n = x_{CG}$$ (210)

$$x_{CG} + \Delta x_m = x_m$$ (211)

Equations (210) and (211) must be satisfied exactly, meaning that the constraints that enforce them must be tight. As will be shown later, the load through the nose gear and main gear is proportional to the distance from the c.g. to the main and nose gear, respectively. Because there is downward pressure on these loads (more load generally means heavier landing gear), there is also downward pressure on the distances $\Delta x_n$ and $\Delta x_m$. Therefore, signomial constraints are used for both relationships:

$$x_n + \Delta x_n \geq x_{CG}$$ (212)

</table>
3. Takeoff Rotation

The aircraft must be able to rotate on its main wheels at takeoff without striking the tail of the fuselage and, similarly, must be able to land on its main gear without striking the tail [31]. This constrains the location of the main gear. More specifically, the horizontal distance between the main gear and the point at which the fuselage sweeps up toward the tail must be sufficiently small, relative to the length of the main gear, such that the angle relative to the horizontal from the main wheels to the upsweep point is greater than the takeoff/landing angles. The result is a signomial constraint that imposes a lower bound on the length of the main gear and the x location of the main gear:

\[
\frac{l_m}{\tan(\theta_{\text{max}})} \geq x_{\text{up}} - x_m
\]  

(219)

4. Tip-Over Criteria

A longitudinal tip-over criterion requires that the line between the main gear and the c.g. be at least 15 deg relative to the vertical such that the aircraft will not tip back on its tail at a maximum nose-up attitude [31]. This puts a lower bound on the x location of the main gear as measured from the nose of the aircraft. Note that tan(\(\phi\)) is a design variable here, instead of \(\phi\), to make the constraint SP-compatible:

\[
x_m \geq (l_m + z_{\text{CG}})\tan(\phi) + x_{\text{CG}}
\]

(220)

\[
\tan(\phi) \geq \tan(\phi_{\text{min}})
\]

(221)

A lateral tip-over constraint is introduced to ensure that an aircraft does not tip over in a turn [30]. The turnover angle is defined as:

\[
\tan \psi = \frac{z_{\text{CG}} + l_m}{\Delta x_m \sin \delta}
\]

(222)

where

\[
\tan \delta = \frac{y_m}{B}
\]

(223)

Using the relationship

\[
\cos \left( \arctan \left( \frac{y_m}{B} \right) \right) = \frac{B}{\sqrt{B^2 + y_m^2}}
\]

(224)

this constraint can be rewritten in not only SP-compatible but GP-compatible form as:

\[
1 \geq \frac{(z_{\text{CG}} + l_m)^2(y_m^2 + B^2)}{(\Delta x_m y_m \tan(\psi))^2}
\]

(225)

Typically, this angle \(\psi\) should be no larger than 63 deg [31]:

\[
\tan(\psi) \leq \tan(\psi_{\text{max}})
\]

(226)

5. Landing-Gear Weight

The total landing-gear system weight is lower-bounded by accounting for the weights of each assembly. An additional weight fraction is used to account for weight that is proportional to the weight of the wheels [32]:

\[
W_{\text{tg}} \geq W_{\text{mg}} + W_{\text{ng}}
\]

(227)

\[
W_{\text{mg}} \geq n_{\text{mg}}(W_{\text{ms}} + W_{\text{mw}}(1 + f_{\text{addg}}))
\]

(228)

\[
W_{\text{ng}} \geq W_{\text{ns}} + W_{\text{nw}}(1 + f_{\text{addg}})
\]

(229)
The weight of each strut for both the main and nose struts is lower-bounded by simplistically assuming a thin-walled cylinder with constant cross-sectional area:

\[ W_{m} \geq 2\pi r_{m} t_{m} l_{m} \rho \sigma_{y} g \]  

(230)

\[ W_{n} \geq 2\pi r_{n} t_{n} l_{n} \rho \sigma_{y} g \]  

(231)

It is assumed that the strut is sized by compressive yield and (more stringently) by buckling, again assuming a thin-walled cylinder. This constrains the area moment of inertia of the strut cross section, which puts upward pressure on the radius and thickness of the struts. The buckling constraint assumes that no side force is exerted on the cylinder, which is perhaps a weak assumption due to forces exerted in braking, for example, and due to the fact that aircraft do not typically land with the main gear struts perfectly normal to the runway surface:

\[ 2\pi r_{m} \sigma_{y} \geq \frac{\lambda_{L} L_{m} N_{s}}{n_{mg}} \]  

(232)

\[ 2\pi r_{n} \sigma_{y} \geq (L_{n} + L_{r_{n}}) N_{s} \]  

(233)

\[ L_{m} \leq \frac{\pi^{2} E I_{m}}{K^{2} I_{m}} \]  

(234)

\[ I_{m} = \pi r_{m}^{4} t_{m} \]  

(235)

\[ L_{n} \leq \frac{\pi^{2} E I_{n}}{K^{2} I_{n}} \]  

(236)

\[ I_{n} = \pi r_{n}^{4} t_{n} \]  

(237)

A machining constraint is used to ensure that the strut walls are not too thin to be fabricated [30]:

\[ \frac{2r_{m}}{t_{m}} \leq 40 \]  

(238)

\[ \frac{2r_{n}}{t_{n}} \leq 40 \]  

(239)

The wheel weights can be estimated using historical relations from [31,32], which are again conveniently in monomial form:

\[ W_{m_{w}} = n_{wps} W_{w_{a,m}} \]  

(240)

\[ W_{n_{w}} = n_{wps} W_{w_{a,n}} \]  

(241)

\[ W_{w_{a,m}} = 1.2 F_{w_{w_{a,m}}}^{0.609} \]  

(242)

\[ F_{w_{m}} = L_{w_{m}} d_{l_{m}} \]  

(243)

\[ L_{w_{m}} = \frac{L_{m}}{n_{mg} n_{wps}} \]  

(244)

\[ W_{w_{a,n}} = 1.2 F_{w_{w_{a,n}}}^{0.609} \]  

(245)

\[ F_{w_{n}} = L_{w_{n}} d_{l_{n}} \]  

(246)

\[ L_{w_{n}} = \frac{L_{n}}{n_{wps}} \]  

(247)

Main gear tire size can also be estimated using statistical relations. The nose gear tires are assumed to be 80% of the size of the main gear tires:

\[ d_{n} = 1.63 L_{w_{w_{m}}}^{0.315} \]  

(248)

\[ w_{n} = 0.104 L_{w_{w_{m}}}^{0.480} \]  

(249)

\[ d_{n} = 0.8 d_{m} \]  

(250)

\[ w_{n} = 0.8 w_{m} \]  

(251)

In addition, simple retraction space constraints are used to ensure that the gear assemblies are not too wide to fit inside the fuselage:

\[ 2w_{m} + 2r_{m} \leq h_{hold} \]  

(252)

\[ 2w_{n} + 2r_{n} \leq 0.8 \text{ m} \]  

(253)

6. Landing-Gear Loads

The maximum static loads through the nose and main gear are constrained by the weight of the aircraft and the relative distances from the c.g. to the main and nose gear, respectively:

\[ L_{n} = \frac{W_{\text{max}} \Delta x_{mg}}{B} \]  

(254)

\[ L_{m} = \frac{W_{\text{max}} \Delta x_{mg}}{B} \]  

(255)

For the nose gear, there is an additional dynamic load due to the braking condition. A typical braking deceleration of \( 3 \text{ m/s}^{2} \) is assumed [31]:

\[ L_{n_{dy}} \geq 0.31 W_{\text{max}} \frac{l_{m}}{B} + z_{CG} \]  

(256)

The nose gear requires adequate load for satisfactory steering performance. A typical desirable range is between 5 and 20% of the total load [31]:

Fig. 10 Illustration showing the extent of coupling between the subsystem models, and the variables that directly couple them.
\[
\frac{L_n}{W_{\text{max}}} \geq 0.05 \quad (257)
\]
\[
\frac{L_n}{W_{\text{max}}} \leq 0.2 \quad (258)
\]

As a preliminary model, the oleo size can be estimated using historical relations that are conveniently in monomial form [31]. The length of the main gear must be greater than the length of the oleo and the radius of the tires:

\[
\eta_s = \frac{1}{L_{\text{land}}} \quad (260)
\]

7. Shock Absorption

Oleo-pneumatic shock absorbers are common to landing gear for large aircraft. Their purpose is to reduce the vertical load on the aircraft at touchdown, and they are typically sized by a hard landing condition. The maximum stroke of the shock absorber can be determined by considering the aircraft’s kinetic energy and the target maximum load [27]:

\[
E_{\text{land}} \geq \frac{W_{\text{max}}}{2g} u_{\text{init}}^2 \quad (259)
\]

\[
\frac{l_{\text{oleo}}}{0.0136} = 2.5S_s \quad (261)
\]

\[
d_{\text{oleo}} = 1.3 \sqrt{\frac{4L_{\text{LG}}L_{m}/n_{\text{eng}}}{p_{\text{oleo}} \pi}} \quad (262)
\]

\[
l_{m} \geq l_{\text{oleo}} + \frac{d_{\text{sa}}}{2} \quad (263)
\]

---

**Fig. 11** Plots illustrating the convergence of the objective function.

a) Total cost vs GP iteration

b) Cost contribution of fuel burn for GP iterations with no relaxed constants. Since all slack variables are equal to one, the fuel burn cost contribution is equivalent to total cost

c) Cost contribution of slack variables and fuel burn vs GP iteration
VIII. Model Solution

Combining all of the previously described system and subsystem models into a single full-aircraft optimization problem allows us to capture the coupled nature of aircraft design. From a practical perspective, the procedure of combining the subsystem models is relatively straightforward because, as mentioned previously, each model is fundamentally just a list of constraints. Coupling models essentially just involves concatenating these lists.

The free variables that directly couple two or more of the subsystem models are illustrated in Fig. 10.

A. Solution Time

The size of the full-system model and therefore its solution time depends on the number of discretizations of the Breguet range model. With two cruise segments, the SP has 824 free variables and takes seven GP solves to converge in a time of 6.2 s, using a standard laptop computer with a 2.5 GHz Intel Core i7 processor.

B. Convergence of the Objective Function

Convergence of the objective function [Eq. (19)] is plotted in Fig. 11a. The total cost can be decomposed into a contribution from slack variables and a contribution from fuel burn. These decompositions are plotted in Fig. 11c. The fuel burn cost contribution for GP iterations three through seven is plotted in Fig. 11b, where it is equivalent to the total cost because all slack variables are equal to 1 after the second GP iteration.

C. Solution Comparison to the Reference Aircraft

The optimal values for a selection of key design variables are presented in Table 13. Discrepancies between computed values and reference aircraft values are largely due to the placeholder engine model, lack of a detailed flight profile, and the lack of a climb flight condition, which particularly affects the sizing of the horizontal tail. Both a detailed engine and flight profile model are the subject of ongoing work. Additionally, total fuel burn is minimized in the presented work, whereas an aircraft manufacturer likely optimizes a more nuanced objective function, including manufacturing cost, maintainability, and the ability to stretch the aircraft in the future. This likely contributes to the discrepancy between the presented values. The ability of the SP aircraft model to robustly solve for alternate objective functions is discussed in future work.

D. Sensitivity to Initial Guess

As mentioned in Sec. 1, signomial programs require an initial guess for the subset of variables that appear either on the greater side of signomial inequality constraints or in signomial equality constraints. The solution was obtained using an initial guess of one for each of these variables. To see how sensitive this solution is to the choice of initial guess, the problem was also solved using an order-of-magnitude initial guess for each variable. Using the better initial guess did not change the solution values and only slightly reduced the solution time (less than 0.1 s), largely because any speed increases are mostly limited to the first GP solve, which constitutes a small portion of total solve time.

E. Sensitivity to Fixed Parameters

The sensitivity of the objective function to each parameter is obtained from the problem’s dual solution, at no additional computational cost. Intuitively, the sensitivity is an estimate of the percentage change in the objective value with a 1% change in the value of the parameter. Select sensitivities are presented in Table 14.

*$Mean values over the discretized cruise.

The sensitivity of the objective function to each parameter is, perhaps unsurprisingly, sensitive to minimum cruise Mach number $M_{\text{min}}$ (0.530) and the range requirement $R_{\text{eq}}$ (1.23). The sensitivity to $W_{\text{avg.gas.total}}$ is 0.544, which shows that uncertainties in assumptions made about payload can have strong effects on aircraft sizing.

Parameters that are primarily devoted to ensuring safety, such as never-exceed speed $V_{\text{ac}}$ and engine y location $Y_{\text{eng}}$, have relatively high sensitivities of 0.425 and 0.510, respectively, giving an example of the safety–performance tradeoff.

The sensitivity to wing maximum lift coefficient $C_{l_{\text{max}}}$ is negative (−0.236) but weakly so due to opposing pressures from takeoff sizing and structural sizing constraints. A higher maximum lift can mean lower wing area for a takeoff sizing case (demonstrated by the strong negative sensitivity on $V_{\text{i}}$ of −0.959), but wing structural constraints mitigate the negative sensitivity because a higher maximum lift coefficient results in greater wing root moments at a given load factor. The same opposing pressures mean that the sensitivity to horizontal
The effects of a lengthening fuselage on the subsystems. The diverging sensitivities to fuselage and vertical tail weights indicate the effect of larger changes in fixed parameters. Solving the optimization problem over a sweep of the parameters of interest is required. With most MDO methods, the computational cost of these sorts of sweeps would be prohibitive, but the speed of SPs largely mitigates this issue. Sweeps allow designers to understand how the objective value and other key variables change with respect to fixed parameters. As an example, 20 aircraft with capacities ranging from 150 to 210 passengers were optimized. The optimal fuel weight and the total weight of the aircraft are plotted in Fig. 12. Each solution in the parameter sweeps gives the values of all free variables and the sensitivities to all fixed parameters. Furthermore, through the addition of dummy variables, the sensitivity to constraints can be determined. For example, the sensitivities to different component weights are plotted in Fig. 13. The decreasing sensitivity to vertical tail weight and increasing sensitivity to fuselage weight in Fig. 13 indicate the effects of a longer fuselage on the fuselage and vertical tail weight trade. As the number of passengers increases, the growing vertical tail moment arm allows for a reduction of the required vertical tail area, which reduces weight and drag. This fuel burn benefit is offset by the fuselage weight growth due to a larger fuselage volume and length, driven especially by the growth of bending material weights as the fuselage lengthens.

F. Solution Behavior with Variation in Fixed Parameters

Sensitivities provide local gradient information about the objective function with respect to variation in fixed parameters. However, if a designer would like to understand the effect of larger changes in fixed parameters, solving the optimization problem over a sweep of the parameters of interest is required. With most MDO methods, the computational cost of these sorts of sweeps would be prohibitive, but the speed of SPs largely mitigates this issue. Sweeps allow designers to understand how the objective value and other key variables change with respect to fixed parameters. As an example, 20 aircraft with capacities ranging from 150 to 210 passengers were optimized. The optimal fuel weight and the total weight of the aircraft are plotted in Fig. 12. Each solution in the parameter sweeps gives the values of all free variables and the sensitivities to all fixed parameters. Furthermore, through the addition of dummy variables, the sensitivity to constraints can be determined. For example, the sensitivities to different component weights are plotted in Fig. 13. The decreasing sensitivity to vertical tail weight and increasing sensitivity to fuselage weight in Fig. 13 indicate the effects of a longer fuselage on the fuselage and vertical tail weight trade. As the number of passengers increases, the growing vertical tail moment arm allows for a reduction of the required vertical tail area, which reduces weight and drag. This fuel burn benefit is offset by the fuselage weight growth due to a larger fuselage volume and length, driven especially by the growth of bending material weights as the fuselage lengthens.

IX. Conclusions

In this work, signomial programming has been used to tackle the multidisciplinary design optimization of a commercial aircraft. More specifically, signomial programming models have been created to find the optimal preliminary sizing of a tube-and-wing-configuration aircraft’s wing, vertical tail, horizontal tail, fuselage, and landing gear. These subsystem models have been combined into a single monolithic signomial program that captures the coupled nature of aircraft design.

In doing this work, signomial programming has been demonstrated as a viable approach to aircraft design optimization, with a wide range of constraints fitting naturally into the required formulation. Though not as rigorous as for geometric programs, the solution method for signomial programs is disciplined and effective. A significant improvement in fidelity over previous geometric programming models has been achieved thanks to the relaxed restrictions on signomial programs. Lagrange multipliers obtained from the solution procedure mean that, in addition to finding an optimal design, the models also give local sensitivities to fixed variables, thus giving insight into the design space.
